1 Motivation

This is a template for an undergraduate or master's thesis. The first sections are concerned with the template itself. If this is your first thesis, consider reading.

2 RISC-V

As the first foundation for my benchmarks and, consequently, this thesis, I will discuss RISC-V and its operational principles.

2.1 Overview

RISC-V is an open-source instruction set architecture first published in May 2011 by A. Waterman et al. [4]. As indicated by its name, it is based on the RISC design philosophy. (TODO: Explain RISC (compare wiki)) Since 2015, the development of RISC-V has been coordinated by the RISC-V International Association, a non-profit corporation based in Switzerland since 2020 [5]. Its objectives include providing an *open* ISA that is freely available to all, a *real* ISA suitable for native hardware implementation, and an ISA divided into a *small* base integer ISA usable independently, for example in educational contexts, with optional standard extensions to support general-purpose software development [1, Chapter 1].

Currently, RISC-V comprises four base ISAs: RV32I, RV64I, RV32E, and RV64E, which can be extended with one or more of the 47 ratified extension ISAs [1, Preface].

(EXTEND: Additional content may be required here) (TODO: Mention little endian?)

For the purposes of this work, I will focus on a subset of the RV64I ISA.

2.2 The RV64I ISA

RV64I is not overly complex, but its structure is essential for understanding the subsequent work presented in this thesis. Therefore, I will explain all elements relevant to my work.

RV64I features 32 64-bit registers, labeled x0-x31, where x0 is hardwired to zero across all bits. Registers x1-x31 are general-purpose and may be interpreted by various instructions as collections of booleans, two's complement signed binary integers, or unsigned integers. Additionally, there is a non accessible register called pc, which serves as the program counter and holds the address of the current instruction [1, Chapters 4.1, 2.1].

In RV64I, memory addresses are 64 bits in size. As the memory model is defined to be single-byte addressable, the address space of RV64I encompasses 2⁶⁴ bytes [1, Chapter 1.4].

Like nearly all standard ISAs of RISC-V, RV64I employs a standard instruction encoding length of 32 bits, or one *word*. Only the compressed extension named C introduces instructions with a length of 16 bits [1, Chapter 1.5], but we will not encounter this special case. All RV64I instructions are encoded in one of the six formats illustrated in Figure 1. These formats may consist of

• The opcode:

The opcode is used to differ between groups of instructions. It also defines the format type of the instruction.

• *rd*:

This is the destination register.

• *funct*3:

This is used to differ between instructions with the same opcode.

31	25 24	20 19	1	5 14	12 11	7	6		0

Figure 1: RV64I encoding formats, used in [1, Chapter 2.3]

• rs1 & rs2:

These are the source registers.

• funct7

:This is used for further distinctions between instructions if there are more than 8 instructions in an opcode group and funct3 does not suffice.

• *imm*:

This is an immediate value. In square brackets after *imm* is designated a subfield of the immediate which is represented by these bits. From these subfields, non-defined lower bits are filled with zeros whereas the highest defined bit is sign extended to fill all non-defined higher bits.

The design of these formats results in the following features:

- Due to RISC-V's little-endian nature, the *opcode*, which encodes the general instruction, is always read first. Further specification of the instruction via funct3 and funct7 is consistently located at the same positions.
- If utilized by the instruction, rd, rs1 and rs2 are also always found in the same locations, simplifying decoding.

Table 1: Subset of RV64I instructions (TODO: Maybe rework, not happy yet)

• The highest bit of *imm* is always bit 31, making it straightforward to sign-extend the immediate value.

The instructions relevant to my work are listed in Table 1

I have divided the instructions in Table 1 into nine groups based on their operations.

LUI and AUIPC move a high immediate into rd. In case of AUIPC, the pc is added onto this.

JAL and JALR instructions are unconditional jumps, where on JAL imm is added onto pc and on JALR imm is added onto rs1 and set as pc. Both link to the next instruction (current pc + 4) in rd.

branch instructions are conditional jumps. rs1 is compared to rs2 and if the comparison holds, imm is added onto pc. The comparison are = for BEQ, \neq for BNE, < for BLT and \geq for BGE. In these instructions, the values in rs1 and rs2 are handled as twos complement integers. The suffix *U in an instruction generally designates an

Instr	Behavior
ADD	rd := rs1 + rs2
SUB	rd := rs1 - rs2
SLT	rd := 1 if $rs1 < rs2$ else $rd := 0$
XOR	$rd := rs1 \oplus rs2$, bitwise
OR	$rd := rs1 \vee rs2$, bitwise
AND	$rd := rs1 \wedge rs2$, bitwise
SLL	rd := rs1 shifted left by $rs2$, new bits are zeros
SRL	rd := rs1 shifted right by $rs2$, new bits are zeros
SRA	rd := rs1 shifted right by $rs2$, sign extend

Table 2: All suffix free operations in RV64I and their behavior. All values are handled either bitwise or as signed twos complement integers

unsigned operation. In this case the values in rs1 and rs2 are handled as unsigned integers. Apart from this, they work as their counterpart without the suffix.

load instructions load values from memory at address (rs1 + imm) into rd, either at Byte, Halfword, Word, or Doubleword length. Again the standard is a sign-extended value and the suffix *U designates the loading of a non sign extended value.

Conversely, store instructions write values from rs2 at the address (rs1 + imm) to memory. Here also the distinction between the different lengths is made and the lowest byte, halfword, word or the whole doubleword is stored at the address.

All further instructions can be seen as generic operations, differentiated by their suffixes. To simplify the explanation process, all operations without any suffix and their behaviour are listed in Table 2. This is almost exactly the group with opcode op, except the SLTU instruction, which is not suffix free. But as all other instructions with the unsigned suffix it behaves as its signed counterpart except from handling both rs1 and rs2 as unsigned integers.

These operations can be extended by the *I suffix which is designated by the opcode op-imm. This exchanges rs2 with imm in the behavior. Again, SLTI can be extended to an unsigned version SLTIU, which behaves as expected. A SUBI instruction does

not exist as it is redundand. Its behavior can be reached by using ADDI with a negative immediate.

Also, the operations ADD, SUB, SLL, SRL and SRA can be extended with the *W suffix. This forms the group with the opcode op - 32. In contrast to the base instructions these new ones behave as if the registers are only 32bit. The result is placed in the low 32 bits of rd and sign extended to full 64bit. Overflows are ignored.

The last group left is the combination of both suffixes *IW with the opcode op-imm-32. The behavior differs from the base instructions, as expected, by a replacement of rs2 with imm and only operating on 32bit. Again, a SUBIW instruction is redundand as a negative immediate with ADDIW archives the same.

Compared to the full RV64I ISA, I left out FENCE, ECALL and EBREAK instructions as without I/O interaction or an environment like an OS or a debugger, these are not needed.

2.3 Simulation of RISC-V

In a previous project, I have written a simulation of this subset of RV64I in C [6]. As I will use it to later on test my BTOR2 model, I explain the inner working of the program here.

First I implemented a structure to represent a simple RISC-V processor

2.3.1 Representing the State of a RISC-V Processor

Of course the state needs a representation for all registers. pc is defined as a 64bit integer, the other 32 registers are implemented as an array, as so each register can be referenced by its number. Also I implemented an array of flags, one for each register, to be able to differ between initialised and non initialised registers. The memory

```
typedef struct memory_cell
{
    uint64_t address;
    uint8_t content;
    struct memory_cell *next_cell;
} memory_cell *next_cell;
} memory_cell;

typedef struct state
{
    uint64_t pc;
    uint64_t regs_values[32];
    bool regs_init[32];
    memory_table *memory;
} state;
```

Figure 2: State representation of a RISC-V processor in the simulation [6]

is build from single memory cells holding each an address and its byte of content. These are cumulated a hashtable "memorytable", hashing on the address. If adding a new cell causes a collision, it is appended to the cells already in the bucket forming a linked list. These structs are shown in Figure 2.

2.3.2 Instruction detection

2.3.3 Instruction execution

2.3.4 Saving the State of a RISC-V Processor

To preserve the current state of a RISC-V processor, both the registers and memory must be stored. For this purpose, I have devised the format shown in Figure 3. The minimal file consists only of the two designators "REGISTERS:" and "MEMORY:", the current pc, and one empty line.

```
1 REGISTERS:
2 PC: current pc in hex
3 x(0 - 31): value of register in hex
4
5 MEMORY:
6 (address in hex): byte, halfword, word or doubleword in hex
```

Figure 3: Construction of .state files

3 BTOR2

The second foundation of my benchmarks is BTOR2, a word-level model checking

format published by A. Niemetz et al. [2].

3.1 Model Checking

(TODO: Write something about model checking...)

3.2 The BTOR2 Language

Generally in BTOR2, every line represents either a sort or a node, where normally the

line number acts as an identifier. A sort behaves similar to a type as with it, either

the length of a bitvector or the size of an array of bitvectors is defined. Nodes on the

other hand represent a value of a defined sort and come as constants, operations or

constraints. These values can later on be referenced by the node identifier, so the

line number. The syntax of BTOR2 can be found at [2, figure 1] and corresponding

operators in [2, table 1]

Key features of BTOR2 include its ability to operate sequentially, which makes

the implementation of a RISC-V structure highly convenient. The main feature is

the state operator, which defines a node that is sequentially updated. With an

init node, this state can be assigned an initial value, and with a next node, the

11

sequentially next state can be defined. Finally, constraints can be used to specify endpoints for a model. These endpoints may indicate that something unintended has occurred or that the intended information has been found. In either case, the resulting model is provided as a witness.

3.3 The BTOR2 Witness

After receiving a witness, it must be interpreted. On the second line of a witness, the constraint that was triggered is specified. Subsequently, for each sequential iteration, the witness first presents—marked with #x, where x is the iteration number—a representation of all states in the current iteration. Second, marked with @x, all inputs for the iteration are listed.

(TODO: Maybe a bit more, its a bit bare bones)

4 Transforming RISC-V to BTOR2

(TODO: explain naming conventions for the model nodes)

This chapter addresses the main problem of the thesis: transforming a RISC-V state into the BTOR2 format for benchmarking purposes. My primary orientation for this endeavor is F. Schrögendorfer's master's thesis, "Bounded Model Checking in Lockless Programs" [3], in which he describes, among other topics, an encoding concept for a minimal machine in a multiprocessor context [3, Chapter 2]. With this, in [3, Chapter 8] he describes a way to encode programs for his machine model into a BTOR2 model. This can not be replicated by me though, as in his model, the full program is known at encoding whilst I want to hold the property of RISC-V programs to self-modify its own code. Therefore, my encoding can not follow his example. (TODO: Einfache benchmarks in seinem btor2 modell schreiben und vergleichen?)

4.1 The Concept

To successfully execute a RISC-V instruction, three fundamental steps must occur in sequence:

- Fetch the current instruction from memory
- Identify the instruction
- Execute the instruction

Due to the fixed instruction length of RISC-V, as mentioned in Section 2.2, fetching the current instruction is straightforward. Ultimately, we want a node that retrieves a word from memory at the location specified by pc.

For basic identification, the opcode must be extracted and checked. Depending on the opcode, further distinctions between instructions require extracting and checking funct3 and, if necessary, funct7. Ultimately, we want a node for each instruction, which holds a boolean value indicating whether this instruction was fetched.

To execute the instruction, we need to extract the values of the immediate imm and, if used, the registers rs1 and rs2. All instructions only modify rd, pc, or memory. Therefore, the next-state logic can be generalized for these three cases.

Memory is only modified when a store instruction is identified. As all store instructions share the same type, computing the memory address is consistent across them. The final step is overwriting the memory at this address.

For the pc, except for jump commands, it always increments to point to the next instruction. The two unconditional jumps, JAL and JALR, must be handled separately. For branch instructions, after determining whether the relevant condition for the instruction holds, we can generalize, as all branch instructions execute the same operation from this point onward.

With rd, generalization across instructions is not feasible. However, we can generalize across all possible registers by adding a check in each register's update function to determine whether the register in question is rd.

4.2 Encoding

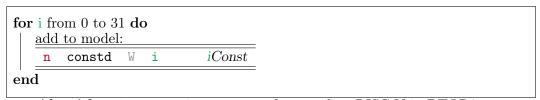

For better visualisation in the BTOR2 code I will mark all sort-ids in grey, all node-ids in red and all non-id numbers blue. As described in the BTOR2 syntax [2, Figure 1], each line can get an accompanying symbol. Sadly those cant be used as an alias to

the line numbers, but for increased clarity, in the following figures I will use them as such aliases. With this I can also start each new figure with the relative line number n and it makes it feasible to describe processes with algorithms. It is implied that n is sufficiently incremented after adding to the model so that ids will not overlap. In the following, I will describe how I construct a BTOR2 model for a RISC-V state file.

4.2.1 Constants

First off, I added the sorts and non-progressive constants needed into the BTOR2 model as seen in Figure 4. This is extended by a set of progressive constants used for comparison e.g. against the register number. Algorithm 1 describes how they are added.

Of note is the Representation of the memory as an array of addressable memory cells of each 1byte. Obviously, the set address space of 16bit is magnitudes away of the expected address space of 64bit, but representing a 64bit addressable memory with its resulting $2^{64}B \approx 18Exabyte$ is not implementable. Therefore, as I needed a feasible amount of memory space, I artificially chose a 16bit address space as a soft minimum. With 65kB and therefore programs with possibly > 10000 instructions I deemed this memory sufficient for most use cases. Despite this, the encoding is implemented in such a way that the address space can be altered with. (TODO: benchmark auswirkungen von memory size)

Figure 5: State representation for encoding

4.2.2 State Representation

The next logical step is defining a representation of a RISC-V state. Tis is straightforward as shown in Figure 5. I also introduced a flag for each register in my code. They track if the register was written to and makes it possible to shorten a state file transformed from a witness to only the relevant registers. As they have no impact on the operation of the BTOR2 model, I will not mention them again.

4.2.3 Initialization

To initialize a state in BTOR2 from a RISC-V state file, the values in the registers must be loaded as constants, and for each memory address mentioned in the state file, the value and address has to be loaded as constants. Due to the inability to represent a full 64bit address space, the shrinking of the address space from state file to BTOR2 model must be handled. I decided to just initialiase the addresses

up to the BTOR2 model address space maximum and cut all others in the state file as I deem this the most predictable behaviour. Everything not mentioned in the state file will be zero-initialised. At last these constants must be used to initialise the state. For the registers this is straight forward, for the memory we must first write all memory addresses into a placeholder array wich then we can use to initialise the real memory. Due to constraints in BTOR2, these constants have to be defined **before** the states, but initialisation with the values must happen after the states. This means that this initialisation process **wrappes around** the state representation. The generation of constants is shown in Algorithm 2, whereas the actual initialization is shown in Algorithm 3.

4.2.4 Fetching the current instruction

To fetch the current instruction, i read the 4 bytes of the instruction and concatenate them as seen in Figure 6

4.2.5 Deconstruction of the instruction

Now having the instruction, we can deconstruct it to extract the opcode, rd, rs1, rs2, funct3, funct7 and imm. For everything apart of imm, this can be done by a shift and a masking. This is shown in Figure 7.

The immediate on the other hand must be first constructed from its subfields, which can be referenced in Figure 1. In the BTOR2 model this looks like in Figure 8. (TODO: Reference to same method in riscvsim) There are three things i want to point out:

First, some of the immediate subfields overlap exactly. I made use of this fact in lines (n + 1) with the overlap of imm[11:5] of I- and S-type, and (n + 21) with J- and B-types imm[10:5] overlap. Second, as described in Section 2.2 the immediate is always sign-extended. To archive this we make arithmetic right shifts, which do

```
truePc \leftarrow value of pc in state file
maxPc \leftarrow \text{number of addresses in BTOR2 model}
pcValue \leftarrow truePc \text{ modulo } maxPc
add to model:
                                 pcConst
               AS
                     pcValue
     constd
for every register x_i do
   if register is initialised in state file then
       registerValue \leftarrow value of x_i
       if registerValue \neq 0 then
           add to model:
                 constd D registerValue
                                                  x_i Const
       end
   end
end
add to model:
                                                    memPH
 (n + 0)
                      Mem
             state
 (n + 1)

Figure 7: Extraction of values from the instruction without imm

sign extension for us and with this pull our highest immediate bit to its correct place. Third, at line (n + 8), for sign extension we must shift right by 19. As this matches the opcode for arithmetic instructions with immediates, so I used this and did not create a new constant.

Now I have *iTypeImm*, *sTypeImm*, *bTypeImm*, *uTypeImm* and *jTypeImm*. But it would be easier to just have one node *imm* where we can reference the immediate value regardless of the instruction. This is done in Figure 9, where first I defined Bools wich check all opcodes that are neither R-type nor I-type. Then I chained if-then-else nodes to catch instructions that are of J-type, U-Type, B-Type or S-type. If the instruction is none of them, I can safely default to I-type as R-type does not handle with an immediate value. At the end I extend *imm* to the 64bit RV64I demands.

At this point I can also extract the values of the designated rs1 and rs2 registers. I show this for rs1 in Figure 4, it is the same for rs2 except that the names must be changed to rs2. Also, the comparison constants can be left out as they are already defined for rs1 and can be referenced from there.

Figure 10: Instruction detection of JALR, LHU and SUBW as described in Algorithm 5

4.2.6 Instruction Detection

For the next-state logic, the only thing left that we need to know is the actual current command. So I defined a check is Instruction for each instruction. As this is quite repetetive, Algorithm 5 describes a generalised approach to reach these Bools. An example for each instruction subgroup in Algorithm 5 can be found in Figure 10. Of course the funct7 checks from the needsf7 subgroup can be reused if multiple instructions use the same funct7.

4.2.7 Next-State Logic

The next state logic is basically the core of the model. Almost everything else works towards this point. The Goal is to create the changes each instruction would make and then only inserting the changes specific to the instruction in the state. Each state node in the model must have an accompanying next node to work as intended. But first the changed values are needed.

Creating all Values of Instruction execution

It would be too long and unnecessary to go through all instructions, as this is simply following the RV64I ISA, but I want to give an example for each group of instructions as they were divided in Table 1. I show this for AUIPC, JALR, BEQ, LHU, SD, ANDI, SLLIW, SLT and SUBW in Figure 11. In this examples one can see multiple overlaps which can

```
add to model:

be used, e.g. the adresses for load and store instructions or the 32bit versions of the word instructions. Also I took SD to show that all other store instructions happen as interim results of preparing SD. It is similar with load instructions, but here we only get overlapping pre-results which each have to be sign extended to the expected 64bit on their own.

With this done we can sort each change to its instruction.

The next Memory

Defining the next memory array is simple. I just cascade through all store instructions with if-then-else nodes and by setting the final 'else' as the current memory array, if no 'if' catches, the array is not changed. All this is shown in Figure 12.

Figure 13: Next-State logic for the pc register

The next pc

For the next pc it looks mostly the same as shown in Figure 13. Only the behaviour if no 'if' catches is different as pc must point to the next instruction to execute. This nextPc was already computed for the JAL and JALR instructions so I reused it. The unconditional jumps also change the value in rd, but this is done in the next subsection.

The next rd

At last the x registers must be updated. The procedure is defined in Figure 6. Whith exeption of x0 this is the same for all these registers. Also it is similar in its procedure as defining the next memory or pc but instead of a hand full of instructions, I have to go over 39 of them as only branch and store instructions do not change rd. Because of this, I took the liberty to not exactly show the cascade for all relevant instructions in Algorithm 6 but only indicate it.

4.2.8 Constraints

The only thing left is to define constraints to end the model checker. First is the intended end of reaching a set number of Iterations. It is shown in Figure 14.

```
add to model:
                     x\overline{0}
    next
                x0
for i from 1 to 31 do
   add to model:
                                                                  newXi-49
                                 isLUI
                                            rdLUI
       (n + 0)
                  ite
                         D
                                                       xi
                         D
                  ite
      (n + 47)
                         D
                                 isSRAW
                                            rdSRAW
                                                       newXi-2
                                                                  newXi-1
                  ite
      (n + 48)
                  eq
                         Bool
                                 rd
                                            iConst
                                                                  isRdXi
      (n + 49)
                                 isRdXi
                                            newX_{i-1}
                                                                  newXi
                  ite
                         D
                                                       xi
      (n + 50)
                                            newXi
                         D
                                 xi
                  next
end
```

Algorithm 6: Next-state logic for all x registers

(n + 6)	eq	Bool	counter	maxIterations	is Max Iter
(n + 7)	bad		is Max Iter		

Figure 14: Constraining the model by iteration count

After this I defined some extra constraints to check for bad instructions. First is checked if the opcode is valid for my model. The second constraint catches if the instruction can not be detected even whilst the opcode is valid. This is shown in Figure 15. The constraint in Figure 16 handles instruction-address-misaligned exceptions for jump instructions.

Of course other constraints can be defined. Options would be to stop on a specific pc or if a register reaches a specified value.

 $\textbf{Figure 16:} \ \ \textbf{Constraining the model on misaligned addresses} \\$

4.3 Testing for Correctness

To test my model, I compared its results to my RISC-V simulators (Section 2.3) results.

With a given state, both the simulation and the BTOR2 model are run. For both the iteration maximum is set to 1. The resulting BTOR2 witness can not be directly compared to the resulting state of the simulation. So I also implemented a simple converter from witness to state [7, src/restate_witness.c]. These two states now can be compared. I have written a shell script for this at [7, sh_utils/compare_iterations.sh]

To generate RISC-V states, I implemented a fuzzer [7, src/state_fuzzer.c] to generate randomised states with one valid instruction at the address of pc. The fuzzer first chooses an instruction to test, on this basis it fills all variable parts of the instruction, e.g. rd or imm. Now all registers relevant to the instruction are filled with a random 64bit value. Also a pc value is generated so that the instruction still fits in the limited address space of the BTOR2 model. At last if a jump instruction was chosen, a possible address misalignment is fixed and an address overflow prevented. The second part is for simplifying later comparison on the resulting states, as now a correct execution of the instruction always results in the exact same resulting state although the differences between simulation and the BTOR2 model.

With this it is possible to start test series. For this I implemented a shell script, too [7, sh_utils/test_btor2_model.sh]. Also, as with big amounts of tests, it becomes harder to keep an overview over failed tests. To counter this I also have written a script to unite all failed tests into one file and also add some not so easy to access information like instruction name or immediate value [7, sh_utils/diff_logger.sh].

I have run around 5.000.000 tests on this model without one failing, so I assume that my implementation is correct.

5 Benchmarks
